

# **Linux DMA in Device Drivers**

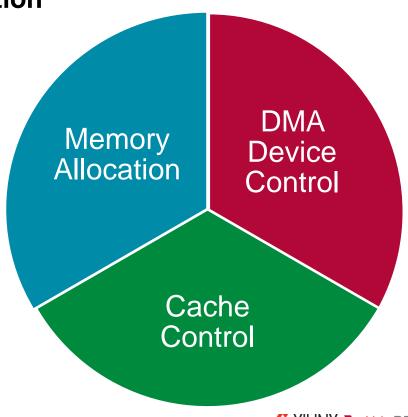

John Linn
Based on Linux kernel 3.14

#### Introduction

- ➤ The goal of this session is to help users understand the Linux kernel DMA framework and how it can be used in a device driver
- > DMA in Linux is designed to be used from a kernel space driver

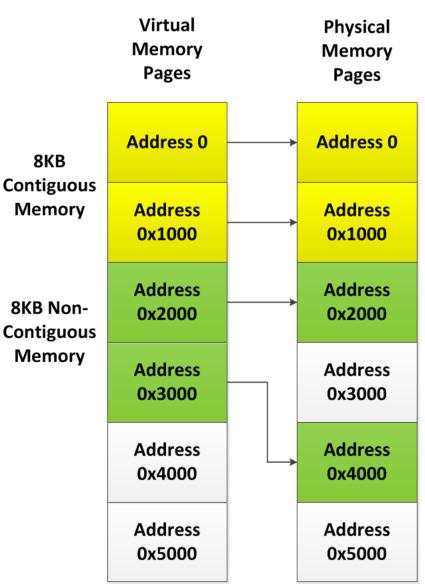

User space DMA is possible and is a more advanced topic that is not covered in this presentation

> The primary components of DMA include the DMA device control together with memory allocation and cache control

#### **Memory Allocation For DMA – Part 1**

- Linux provides memory allocation functions in the kernel
- ➤ The vmalloc() function allocates cached memory which is virtually contiguous but not physically contiguous
  - Not as useful for DMA without an I/O MMU
  - Zyng does not have an I/O MMU
- **➤ The kmalloc() function allocates** cached memory which is physically contiguous
  - It is limited in the size of a single allocation
  - Testing showed 4 MB to be the limit, but it might vary with kernels

8KB

Memory

#### **Memory Allocation For DMA – Part 2**

- ➤ The dma\_alloc\_coherent() function allocates non-cached physically contiguous memory
  - The name coherent can be a confusing name (for me anyway)
  - The CPU and the I/O device see the same memory contents without any cache operations
  - Accesses to the memory by the CPU are the same as a cache miss when the cache is used
  - The CPU does not have to invalidate or flush the cache which can be time consuming
  - This function is the intended function for DMA memory allocation
  - There is another function, dma\_alloc\_noncoherent() but it's not really implemented so don't use it

#### **Boot Time Memory Setup**

- ➤ Memory can be reserved such that the kernel does not use it
  - MEM=512M on the kernel command line causes it to use only 512M of memory
  - The device tree memory can also be changed
- ➤ This is the oldest method allowing large amounts of memory to be allocated for DMA
- ➤ Drivers use io\_remap() to map the physical memory address into the virtual address space
- There are multiple versions io\_remap() which allow cached and non-cached
- ➤ These functions don't allocate any memory, they only map the memory into the address space in the page tables
- ➤ The Linux io\_remap() function causes the memory to be setup as Device Memory in the MMU which should be slower than Normal Memory

## **Cortex A9 Memory Attributes – Device Memory**

- The Zynq TRM explains the details on pages 70 and 82
- ➤ Each page of memory in Linux is setup with memory attributes based on its specific purpose
- ➤ The number and size of accesses are preserved, accesses are atomic, and will not be interrupted part way through
- ▶ Both read and write accesses can have side-effects on the system.
  Accesses are never cached
- Speculative accesses are never be performed
- Accesses cannot be unaligned
- ➤ The order of accesses arriving at Device memory is guaranteed to correspond to the program order of instructions which access device memory
- ➤ A write to Device memory is permitted to complete before it reaches the peripheral or memory component accessed by the write

# **Cortex A9 Memory Attributes – Normal Memory**

- The processor can repeat read and some write accesses
- ➤ The processor can pre-fetch or speculatively access additional memory locations, with no side-effects (if permitted by MMU access permission settings)
- ➤ The processor does perform speculative writes
- Unaligned accesses can be performed
- ➤ Multiple accesses can be merged by processor hardware into a smaller number of accesses of a larger size

# **Contiguous Memory Allocator (CMA)**

- This is a newer feature of the kernel that some people may not know about
- There had been a lot of demand for larger memory buffers needed for many applications including multimedia
- > CMA came into the kernel at version 3.5, about 2 years ago
- > Is only accessible in the DMA framework via dma\_alloc\_coherent()
- Allows very large amounts of physically contiguous memory to be allocated
- Defaults to small amounts
  - Can be increased on the kernel command line (CMA=) which doesn't require a kernel rebuild
  - Can be increased in the kernel configuration

## **CMA Kernel Configuration**

- The Xilinx kernel has CMA turned on by default, but this may vary with kernel versions
- Note that the
  Contiguous Memory
  Allocator must be
  turned on to see the
  configuration options in
  the device drivers
  configuration for DMA
  CMA (next slide)

#### **Linux Kernel Details For DMA**

- ➤ A descriptor is used to describe a DMA transaction such that a single data structure can be passed in an API.
  - A descriptor can also describe a DMA transaction to a DMA core such as the AXI DMA when it is built to use scatter gather
- ➤ A completion is a lightweight mechanism which allows one thread to tell another thread that a task is done
- ➤ A tasklet implements deferrable functionality and replaces older bottom half mechanisms for drivers
  - A function can be scheduled to run at a later time with a tasklet
- ➤ A cookie is an piece of opaque data which is returned from a function, then passed to yet a different function communicating information which only those functions understand
  - A DMA cookie is returned from dmaengine\_submit() and is passed to dma\_async\_is\_tx\_complete() to check for completion of a specific DMA transaction
  - DMA cookies may also contain a status of a DMA transaction

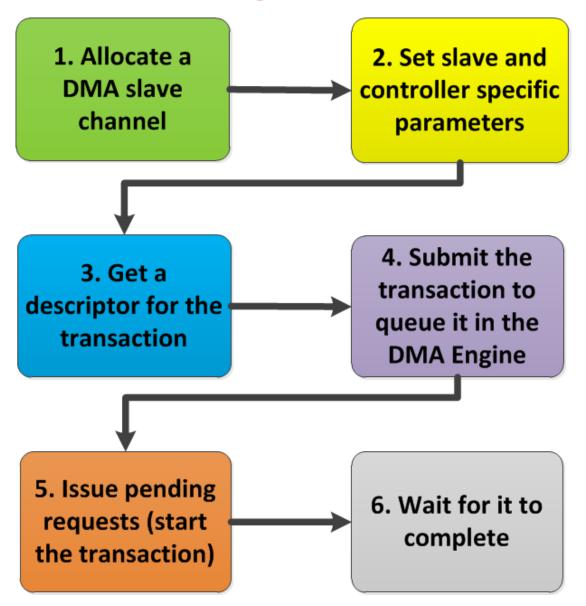

#### **Linux DMA Engine**

- ➤ A driver, dmaengine.c, along with Xilinx DMA drivers, is located in drivers/dma of the kernel
- Documentation about this seems to be limited
  - In kernel: Documentation/dmaengine.txt
  - No other good information on the web

- > The Xilinx kernel has the DMA engine driver turned on by default
  - The Xilinx DMA core drivers are only visible in the configuration when they are enabled
- > The DMA test for the AXI DMA cores in the Xilinx kernel uses the DMA engine slave API
  - This test code is pretty complex with multiple threads such that it's not easy to get down to the basics
  - The tests are also located in drivers/dma (axidmatest.c)

- ➤ The DMA Engine driver works as a layer under the Xilinx DMA drivers using the slave DMA API
  - It appears that slave may refer to the fact that the software initiates the DMA transactions to the DMA controller hardware rather than a hardware device with integrated DMA initiating a transaction
- > Drivers which use the DMA Engine driver are referred to as a client
- > The API designed to handle complex DMA with scatter gather
  - The lab exercise for this session is only using simple DMA to minimize complexity

The slave DMA usage consists of following these steps.

- ➤ Client drivers typically need a channel from a particular DMA controller only and even in some cases a specific channel is desired
- > The function dma\_request\_channel() is used to request a channel
  - A channel allocated is exclusive to the caller
- ➤ The function dma\_release\_channel() is used to release a channel
- ➤ The dmaengine\_prep\_slave\_single() function gets a descriptor for a DMA transaction
  - This is really converting a single buffer without a descriptor to use a descriptor
  - Other functions are provided which allow other DMA modes including cyclic and interleaved modes

- ➤ The dmaengine\_submit() function submits the descriptor to the DMA engine to be put into the pending queue
  - The returned cookie can be used to check the progress
- ➤ The dma\_async\_issue\_pending() function is used to start the DMA transaction by issuing a pending DMA request and wait for callback notification
  - If channel is idle then the first transaction in queue is started and subsequent transactions are queued up
  - On completion of each DMA operation, the next in queue is started and a tasklet triggered. The tasklet will then call the client driver completion callback routine for notification, if set.

# Allocating a Channel Example

A private channel is not affected by processing for other channels dma\_cap\_mask\_t mask; dma\_cap\_zero(mask); dma\_cap\_set(DMA\_SLAVE | DMA\_PRIVATE, mask); chan = dma\_request\_channel(mask, NULL, NULL); // application specific processing // with the channel A more specific dma\_release\_channel(chan); channel can be requested with a filter

- > Set up the capabilities for the channel that will be requested
- ➤ Request the DMA channel from the DMA engine
- > Release the channel after the application is done with it

# **Starting A DMA Transfer Example**

- 1. Allocate a 1KB buffer of cached contiguous memory
- 2. Cause the buffer to be ready to use by the DMA including any cache operations required
- 3. Create a descriptor for the DMA transaction
- 4. Setup the callback function for the descriptor
- 5. Queue the descriptor in the DMA engine

#### **Linux Asynchronous Transfer API**

- ➤ The async\_tx API provides methods for describing a chain of asynchronous bulk memory transfers/transforms with support for inter-transactional dependencies
- > It is implemented as a dmaengine client that smooths over the details of different hardware offload engine implementations
- ➤ Code that is written to the API can optimize for asynchronous operation and the API will fit the chain of operations to the available offload resources
- ➤ The dma\_async\_issue\_pending() function starts the DMA transaction
  - The DMA engine calls the callback function that was supplied with the submit function when the transfer is complete
- ➤ The dma\_async\_is\_tx\_complete() function checks to see if the DMA transaction completed

## **Waiting For DMA Completion Example**

```
unsigned long timeout = msecs_to_jiffies(3000);
enum dma status status;
struct completion cmp;
init_completion(&cmp);
dma_async_issue_pending(chan);
timeout = wait for completion timeout(&cmp,
                                    timeout);
status = dma_async_is_tx_complete(chan, cookie,
                                    NULL, NULL);
if (timeout == 0) {
         // timeout processing
} else if (status != DMA_COMPLETE) {
         if (status == DMA_ERROR) {
                  // error processing
```

- ➤ Initialize the completion so the DMA engine can indicate when it's done
- ➤ Cause the DMA engine to start on any pending (queued) work
- ➤ Wait for the DMA transfer to complete
- **→** Get the status of the DMA transfer
- The transfer could have timed out or completed, with an error or OK

#### Requesting A Specific DMA Channel

- ➤ The dma\_request\_channel() function provides parameters to allow a specific channel to be requested when there are multiple channels
  - struct dma\_chan \*dma\_request\_channel(dma\_cap\_mask\_t mask, dma\_filter\_fn filter\_fn, void \*filter\_param)
- > dma\_filter\_fn is defined as:
  - typedef bool (\*dma\_filter\_fn)(struct dma\_chan \*chan, void \*filter\_param)
  - the filter\_fn routine will be called once for each free channel which has a capability in mask
  - filter\_fn is expected to return 'true' when the desired DMA channel is found
- ➤ The DMA channel unique ID is defined by the DMA driver using the DMA Engine
  - For Xilinx, the AXI DMA, AXI CDMA, and AXI VDMA drivers
  - They use a 32 bit word which is made up of the device id from the device tree for the channel together with the channel direction and a Xilinx ID

# Requesting A Specific Channel Example

```
#include linux/amba/xilinx dma.h>
u32 device_id = <device-id from device tree> << XILINX_DMA_DEVICE_ID_SHIFT
u32 match:
                                                                           4 bits are
                                                                           available
static bool filter(struct dma_chan *chan, void *param)
                                                                        allowing IDs 0 -
                                                                        15, they default
                                                                        to 0 in the device
         if (*((int *)chan->private) == *(int *)param)
                                                      The
                                                                             tree
                   return true;
                                                      Xilinx
         return false:
                                                     unique
direction = DMA MEM TO DEV;
match = (direction & 0xFF) | XILINX_DMA_IP_DMA | device_id);
chan = dma_request_channel(mask, filter, (void *)&match);
```

- ➤ A filter function determines if the channel matches the desired channel
- **▶** Set up the criteria for the channel being requested
- ➤ Request the channel specifying the filter function and the match criteria

#### **OCM** and **DMA**

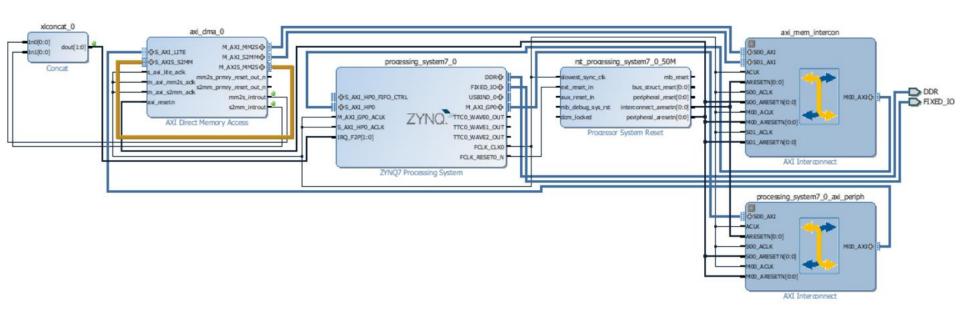

- > The zynq BSP includes a general purpose allocator for OCM
  - arch/arm/mach-zynq/zynq\_ocm.c
- ▶ It maps the memory in the MMU as device memory rather than normal memory which is typically slower
- > The API is different, but simple, and there's minimal documentation
  - Include/linux/genalloc.h
- ➤ Getting a handle to the pool is the toughest part as you need to look it up thru the device tree node
- ➤ The function gen\_pool\_dma\_alloc() is used to allocate a block of memory from the pool
- ➤ The driver works for OCM mapped low or high in memory as it reads the SLCR to determine where it's located

## **DMA With Accelerator Coherency Port (ACP)**

- ➤ When DMA is connected to the ACP port of Zynq the DMA transactions can be cache coherent such that software does not need to worry about the caches
- Cache operations in software can be a signficant amount of processing for large buffers
- ➤ There are tradeoffs to be made as the DMA transactions can also disrupt the CPU caches such that there could be performance impacts to the software

#### **Hardware System For Lab**

➤ Using AXI DMA without scatter gather, with the transmit stream looped back to the receive stream
